ABSTRACT: We compare the sensitivity of precision measurements of lepton flavour observables to the reach of the LHC in a case study of lepton-flavour violating operators of dimension six with two leptons and two quarks. For light quarks precision measurements always yield the more stringent constraints. The LHC complements precision measurements for operators with heavier quarks. Competitive limits can already be set on the cutoff scale $\Lambda > 600\text{--}800\text{ GeV}$ for operators with right-handed τ leptons using the LHC run 1 data.

1 Introduction

The discovery of the 125 GeV Higgs boson [1, 2] in 2012 at the Large Hadron Collider (LHC) has completed the description of the highly successful Standard Model (SM) of particle physics. However, a number of experimental observations and theoretical arguments, such as the origin of neutrino masses, the existence of dark matter, the hierarchy problem and the strong CP problem, can not be accommodated within the SM. Many theoretical proposals addressing these issues generally lead to lepton flavour violating (LFV) processes which are theoretically forbidden in the SM by accidental symmetries. The prime examples are models of neutrino mass. The observation of neutrino oscillations [3] undeniably showed that individual lepton number is not conserved. Thus LFV processes, such as $\mu \rightarrow e\gamma$, may exist. In the minimal type-I seesaw model [4], these processes are suppressed by unitarity and far out of current and future experimental reach. However, in the other two seesaw

models [5, 6] and also in radiative neutrino mass models [7], LFV processes enjoy more freedom and their rates can be large enough to be tested. Other examples include but are not limited to (R -parity violating) supersymmetric models [8] and Z' models [9].

The observation of these LFV processes will definitely shed light on the deeper underlying physics, while the non-observation surely places stringent constraints on the model parameters of the proposed theories. The classical experiments try to search for very rare processes such as $\mu^- \rightarrow e^- \gamma$, $\mu^- \rightarrow e^- e^+ e^-$, μ - e conversion in nuclei and rare τ and LFV meson decays at MEG [10], Mu3e [11], Mu2E [12, 13], COMET [14, 15], SINDRUM [16], B-factories [17, 18], et al. We will refer to these experiments as *precision measurements* due to the ultra-high experimental sensitivities. Meanwhile, LFV processes can also occur at collider experiments with a relatively low SM background. For example, in supersymmetric models squarks and gluinos can be produced at the Tevatron or the LHC with subsequent LFV decays in a cascade decay chain via sleptons. Of this type of collider tests, we will focus on *the LHC* since the results are generally the best ones.

So far such LFV processes have not been observed from precision measurements. At the LHC, the CMS experiment recently reported a 2.4σ anomaly in the $h \rightarrow \mu \tau$ decay [19], while the analysis of ATLAS [20] is consistent with the SM and the CMS result. All these experimental results suggested that the energy scale Λ where new physics emerges are rather high and much larger than the electroweak scale. Therefore we can adopt a simple formalism to interpret the experimental results, namely the effective operators.

In light of the LHC particularly interesting operators are the ones with two quarks and two leptons, because they allow for relatively large cross sections and clean signatures with low SM background. There are ten different gauge invariant operators with two quarks and two leptons, denoted by representations of $SU(2)_L$, following the discussion in refs. [21, 22]. After electroweak symmetry breaking, the gauge-invariant operators induce different contributions to the four-fermion interactions of neutrinos, charged leptons and quarks, which directly enter the relevant physical processes. Constraints obtained for the individual four-fermion interactions can be translated to constraints on the gauge-invariant effective operators by using the most stringent constraint of the generated four-fermion interactions of quarks and leptons. We consider the $SU(2)_L$ invariant operators, obtain the corresponding effective four fermion interactions and determine the most stringent constraints both from precision experiments and the LHC. Previous studies [23, 24] of effective operators with two quarks and two leptons focused on constraints from precision experiments and did not aim to explore the potential of the LHC.

The paper is organised as follows: in section 2 we discuss the LFV effective operators and choose one type for our case study. Although we restricted ourselves to one operator, operator mixing will induce other operators. We discuss QCD renormalization group (RG) corrections in section 3. Then we study the constraints on the chosen operator from precision measurements in section 4. In section 5, we recast the relevant study on the LFV processes from the LHC and draw the current limits and also the future projection at Run 2. We summarise and discuss our results in section 6. Section 7 is devoted to the conclusion. Technical details are collected in the appendix.

Figure 1. Feynman diagram for the operator with top-quark bilinear to generate LFV final states at the LHC.

2 Effective operators

Following the general classification of dimension six operators [21, 22], there are 10 dimension six operators with two quark and two lepton fields neglecting the flavour structure

$$\mathcal{Q}_{lq}^{(1)} = (\bar{L}\gamma_\mu L)(\bar{Q}\gamma^\mu Q), \quad \mathcal{Q}_{lq}^{(3)} = (\bar{L}\gamma_\mu \tau^I L)(\bar{Q}\gamma^\mu \tau^I Q), \quad (2.1)$$

$$\mathcal{Q}_{eu} = (\bar{\ell}\gamma_\mu \ell)(\bar{u}\gamma^\mu u), \quad \mathcal{Q}_{ed} = (\bar{\ell}\gamma_\mu \ell)(\bar{d}\gamma^\mu d), \quad (2.2)$$

$$\mathcal{Q}_{lu} = (\bar{L}\gamma_\mu L)(\bar{u}\gamma^\mu u), \quad \mathcal{Q}_{ld} = (\bar{L}\gamma_\mu L)(\bar{d}\gamma^\mu d), \quad \mathcal{Q}_{qe} = (\bar{Q}\gamma_\mu Q)(\bar{\ell}\gamma^\mu \ell), \quad (2.3)$$

$$\mathcal{Q}_{ledq} = (\bar{L}^\alpha \ell)(\bar{d}Q^\alpha), \quad \mathcal{Q}_{lequ}^{(1)} = (\bar{L}^\alpha \ell)\epsilon_{\alpha\beta}(\bar{Q}^\beta u), \quad (2.4)$$

$$\mathcal{Q}_{lequ}^{(3)} = (\bar{L}^\alpha \sigma_{\mu\nu} \ell)\epsilon_{\alpha\beta}(\bar{Q}^\beta \sigma^{\mu\nu} u), \quad (2.5)$$

where α , and β are $SU(2)_L$ indices.

In general, the quark bilinears can be any combination of flavours and the leptonic bilinear has to be flavour off-diagonal to explain LFV. Various combinations of quark flavours will involve different mesons in the analysis. To cover the whole spectra of mesons is definitely a mission that can not be contained in this single work. Thus we will only start with quark bilinears of same flavours, where we expect the weakest constraints from precision experiments. Among those, the operator with the top quark pair bilinear can only contribute at one-loop at the LHC as shown in figure 1, which leads to an effective dimension 7 operator at low energies with two gluons field strength tensors coupled to a lepton bilinear. This operator has completely different flavour constraints from other operators with lighter quark bilinears. Thus we will restrict ourselves to a study of effective operators with the first five flavour quarks and leave the operator with top quarks for future study.

Both t -channel scalar exchange and s -channel vector boson exchange generate operators with vector bilinears, which have been studied intensively in refs. [23, 24] in terms of effective four fermion interactions. Thus, we will take the operators generated via an s -channel scalar exchange \mathcal{Q}_{ledq} and $\mathcal{Q}_{lequ}^{(1)}$ in eq. (2.4) with Wilson coefficients Ξ^d and Ξ^u , respectively, as a fresh example to demonstrate our study of the sensitivity with precision measurements and the LHC

$$-\mathcal{L} = \Xi_{ij,kl}^d (\mathcal{Q}_{ledq})_{ij,kl} + \Xi_{ij,kl}^u (\mathcal{Q}_{lequ}^{(1)})_{ij,kl} + \text{h.c.} \quad (2.6)$$

They, for instance, are generated in two Higgs doublet models with tree-level flavour violation [25–28]. We will, however, be agnostic about the underlying UV completion and will study the effective operators without any theoretical prejudice.

Specifically, we exemplify the possibility to test effective operators \mathcal{Q}_{ledq} , $\mathcal{Q}_{lequ}^{(1)}$ with two leptons $\ell_{i,j}$ and two same-flavour quarks q_k besides the top quark, t , at the LHC and in precision experiments. It is straightforward to extend the study to operators with a different Lorentz structure.

Writing the $SU(2)_L$ structure explicitly, the operators read

$$(\mathcal{Q}_{ledq})_{ij,kl} = (\bar{L}_i^\alpha \ell_j)(\bar{d}_k Q_l^\alpha) = (\bar{\nu}_{Li} \ell_{Rj})(\bar{d}_{Rk} u_{Ll}) + (\bar{\ell}_{Li} \ell_{Rj})(\bar{d}_{Rk} d_{Ll}), \quad (2.7)$$

$$\left(\mathcal{Q}_{lequ}^{(1)}\right)_{ij,kl} = (\bar{L}_i^\alpha \ell_j) \epsilon_{\alpha\beta} (\bar{Q}_k^\beta u_l) = (\bar{\nu}_{Li} \ell_{Rj})(\bar{d}_{Lk} u_{Rl}) - (\bar{\ell}_{Li} \ell_{Rj})(\bar{u}_{Lk} u_{Rl}) \quad (2.8)$$

and thus lead to two effective four fermion interactions. We define the Wilson coefficients of the effective four fermion interactions Ξ^{Nu} , Ξ^{Nd} , Ξ^{Cu} , Ξ^{Cd} as follows

$$\begin{aligned} \mathcal{L}_{4f} = & \Xi_{ij,kl}^{Cd} (\bar{\nu}_{Li} \ell_{Rj})(\bar{d}_{Rk} u_{Ll}) + \Xi_{ij,kl}^{Nd} (\bar{\ell}_{Li} \ell_{Rj})(\bar{d}_{Rk} d_{Ll}) \\ & + \Xi_{ij,kl}^{Cu} (\bar{\nu}_{Li} \ell_{Rj})(\bar{d}_{Lk} u_{Rl}) + \Xi_{ij,kl}^{Nu} (\bar{\ell}_{Li} \ell_{Rj})(\bar{u}_{Lk} u_{Rl}). \end{aligned} \quad (2.9)$$

They are related to the Wilson coefficients in the unbroken theory via

$$\Xi_{ij,kl}^{Nd} = U_{ii'}^{\ell*} V_{ll'}^d \Xi_{i'j,k'l'}^d, \quad \Xi_{ij,kl}^{Cd} = U_{ii'}^{\nu*} V_{ll'}^u \Xi_{i'j,k'l'}^d, \quad (2.10)$$

$$\Xi_{ij,kl}^{Nu} = -U_{ii'}^{\ell*} V_{kk'}^{u*} \Xi_{i'j,k'l}^u, \quad \Xi_{ij,kl}^{Cu} = U_{ii'}^{\nu*} V_{kk'}^{d*} \Xi_{i'j,k'l}^u, \quad (2.11)$$

where the unitary matrices $U^{\ell,\nu}$ and $V^{u,d}$ relate the quark and lepton states in the basis where the dimension six operator is defined to their mass eigenstates denoted by subscript m , i.e.

$$\nu = U^\nu \nu_m, \quad \ell = U^\ell \ell_m, \quad u = V^d u_m, \quad d = V^d d_m. \quad (2.12)$$

In the following discussion we choose the charged leptons to be diagonal, i.e. $U^\ell = \mathbf{1}$ and thus U^ν becomes the PMNS matrix U . Furthermore, we choose the Wilson coefficients $\Xi^{Nu,Nd}$ to be diagonal in the quark sector. This choice implies that there are no flavour changing neutral currents at tree level. In case of operator \mathcal{Q}_{ledq} , this implies $V^u = \mathbf{1}$ and V^d becomes the CKM matrix V . Similarly for operator $\mathcal{Q}_{lequ}^{(1)}$ we find $V^d = \mathbf{1}$ and $V^u = V^\dagger$. We use the current best-fit values from the UTfit collaboration [29] for the CKM matrix and the ones of the nu-fit collaboration [30] for the PMNS matrix assuming that all leptonic CP phases vanish.

Generally, however, those operators are accompanied by operators with neutral current quark-flavour-violating (QFV) operators. We will also quote limits from these induced operators. In particular, we parameterize the Wilson coefficients of the accompanying QFV operators by (no summation on the right-hand side)

$$\Xi_{ij,kl}^u = \lambda \Xi_{ij,ll}^u V_{kl}, \quad \Xi_{ij,kl}^d = \lambda \Xi_{ij,kk}^d V_{kl} \quad (2.13)$$

for up-type and down-type quarks, where λ indicates the mixing induced from matching to the full theory, which is normalised to the corresponding CKM mixing matrix element.

All Wilson coefficients are fixed at the scale $\mu = 1 \text{ TeV}$. Thus in order to make connection with results from low-energy precision experiments, we have to include RG corrections.

Figure 2. Relevant diagrams for QCD corrections, where q collectively stands for up- and down-quarks.

3 Renormalization group running

Particularly QCD corrections to the operators are important due to the size of the strong interactions. We follow the discussion in ref. [31] to include QCD corrections at next-to leading order to the operators. We take into account the mass thresholds of the quarks and match the effective theories with n_F quark flavours at the pole mass of each quark. As there is no operator mixing for the two quark-two lepton operators from QCD running, the next-to leading order QCD correction simplifies tremendously and the Wilson coefficients at a scale μ are related to the ones at a scale μ_0 via

$$\Xi(\mu) = \Xi(\mu_0) \left(\frac{\alpha_s(\mu)}{\alpha_s(\mu_0)} \right)^{\frac{\gamma_0}{2\beta_0}}. \quad (3.1)$$

The relevant coefficients β_0 and γ_0 can be directly read from the beta functions of Ξ

$$\frac{d\Xi}{d \ln \mu} = -\gamma_0 \frac{\alpha_s}{4\pi} \Xi \quad (3.2)$$

and the one-loop beta function of the strong coupling

$$\frac{d\alpha_s}{d \ln \mu} = -2\beta_0 \frac{\alpha_s^2}{4\pi}. \quad (3.3)$$

A straightforward calculation shows

$$\beta_0 = 11 - 2n_F/3 \quad \text{and} \quad \gamma_0 = 6C_2(3), \quad (3.4)$$

where $C_2(3) = 4/3$ is the quadratic Casimir invariant of the fundamental representation. The relevant diagrams of QCD corrections to the quark propagator and the effective vertex are shown in figure 2.

We use the Mathematica code RunDec [32] to obtain the strong coupling at the different mass scales, which we use to evaluate the running of the Wilson coefficients. Given the large uncertainty of the LHC analysis, we only use the two loop QCD RG equations and match the effective theories at one-loop.

4 Existing flavour physics constraints

There are already several constraints on the operators in eq. (2.6) with same-flavour quarks from existing flavour experiments. The main constraints are from μ - e conversion, LFV neutral meson decays, leptonic charged pseudoscalar decays and semi-leptonic τ -decays.

We do not take into account the recent hints for new physics in different B -decays measured at LHCb [33–35] or the recent hint for lepton flavour non-universality in $B \rightarrow D^* \tau \nu$ measured by BaBar [36], Belle [37], and LHCb [38]. An explanation of these hints for new physics requires operators with quark flavour violation. See ref. [39] for a recent study using effective operators.

We define the Wilson coefficients $\Xi_{ij,kk}^{u,d}$ with an arbitrary phase at the scale $\mu = 1 \text{ TeV}$ and evolve them down to the scale of the relevant process, like the mass of the τ lepton or the heavy quark of the decaying meson. For μ - e conversion and decays of light mesons with masses below 1 GeV, we evaluate the operator at $\mu = 1 \text{ GeV}$, where the operators are matched to chiral perturbation theory, but we neglect any additional quantum corrections in chiral perturbation theory for simplicity. The masses, decay constants, and mixing angles of the considered mesons are summarised in appendix A. Unless stated otherwise we use the experimental values reported in ref. [40]. We vary the phase of the Wilson coefficient in steps of 1° and report the range of obtained limits. We quote all limits in terms of the cutoff scale Λ of the effective operators, i.e.

$$\Lambda \equiv \Xi^{-1/2}. \quad (4.1)$$

4.1 μ - e conversion

The conversion of μ - e in nuclei is probed for several different nuclei, like gold (Au), titanium (Ti), and lead (Pb). So far no observation of the process has been made. This places a stringent limit on the dimensionless μ - e conversion rate defined as,

$$R_{\mu e}^{(A,Z)} \equiv \frac{\Gamma(\mu^- + (A, Z) \rightarrow e^- + (A, Z))}{\Gamma(\mu^- + (A, Z) \rightarrow \nu_\mu + (A, Z - 1))}, \quad (4.2)$$

where A and Z are the mass number and the atomic number of the nuclei. The denominator of eq. (4.2) denotes the well-measured muon capture rate and the numerator is the muon conversion rate calculated with

$$\Gamma(\mu^- + (A, Z) \rightarrow e^- + (A, Z)) = |\Xi_{ij,kk}^{Nu, Nd}|^2 \times \mathcal{F} \times \frac{p_e E_e (\mathcal{M}_p + \mathcal{M}_n)^2}{2\pi}, \quad (4.3)$$

where p_e and E_e is the momentum and energy of the final electron, and $\mathcal{M}_{p,n}$ are the nuclear matrix elements. We follow ref. [41] in the analysis and list both the muon total capture rates and the nuclear matrix elements in table 1. The factor \mathcal{F} parameterizes the interaction between the charged lepton current and the nuclei,

$$\mathcal{F} = \left| \alpha_{SS}^{(0)} + \alpha_{SS}^{(3)} \frac{\mathcal{M}_p - \mathcal{M}_n}{\mathcal{M}_p + \mathcal{M}_n} \right|^2 + \left| \alpha_{PS}^{(0)} + \alpha_{PS}^{(3)} \frac{\mathcal{M}_p - \mathcal{M}_n}{\mathcal{M}_p + \mathcal{M}_n} \right|^2, \quad (4.4)$$

where parameters with superscripts 0 and 3 are related to isospin singlet and triplet respectively. It can be described with two methods, i.e. direct nuclear mediation and meson exchange mediation. Currently the relative strength of the two mechanisms is not known and for simplicity we separately consider them to obtain a limit and we expect that the actual limit will lie in between.

	^{48}Ti	^{197}Au	^{208}Pb
p_e/fm^{-1}	0.529	0.485	0.482
$\mathcal{M}_p/\text{fm}^{-3/2}$	0.104	0.395	0.414
$\mathcal{M}_n/\text{fm}^{-3/2}$	0.127	0.516	0.566
$\Gamma(\mu^- N \rightarrow \nu_\mu N)/10^6 s^{-1}$	2.60	13.07	13.45
$R_{\mu e}^{\text{max}}$	4.3×10^{-11} [16]	7.0×10^{-13} [44]	4.6×10^{-11} [45]
$\bar{u}u$	1100 [870]	2100 [1700]	760 [610]
$\bar{d}d$	1100 [930]	2200 [1900]	780 [680]
$\bar{s}s$	480 [-]	950 [-]	340 [-]
$\bar{c}c$	150 [-]	290 [-]	110 [-]
$\bar{b}b$	84 [-]	170 [-]	61 [-]

Table 1. Parameters for calculation of μ - e conversion rate and the constraints on the cutoff scale Λ [TeV] from μ - e conversion in nuclei using direct nuclear mediation [meson exchange mediation]. We obtain the same constraints for right-handed and left-handed operators. Similarly the constraints are symmetric in the leptons and it does not depend on the lepton bilinear $\bar{\mu}P_L e$ vs. $\bar{e}P_L \mu$.

The direct nuclear mediation describes the interaction at the quark level, while the meson exchange mediation uses meson fields formed from the quark bilinear to mediate the interaction between the charged lepton and the nuclei. With direct nuclear mediation, the parameters $\alpha_{rS}^{(0,3)}$ are given by

$$\alpha_{rS}^{(0,3)} = \frac{1}{4} \times \eta_{rS}^q \times \begin{cases} G_S^{(0)}, G_S^{(3)} & q = u \\ G_S^{(0)}, -G_S^{(3)} & q = d \\ G_S^q, 0 & q = c, s, b \end{cases}, \quad (4.5)$$

where $r = S, P$, $G_S^{(0,3)} = (G_S^u \pm G_S^d)/2$, and the factor of $1/4$ in $\alpha_{rS}^{(0,3)}$ comes from the two projection operators in the quark bilinear and the lepton bilinear. η_{rS}^q takes -1 for $r = P$ with $\Gamma_l = P_L$ and takes 1 in all other cases. The nucleon form factors take the following values [42, 43]

$$G_S^u = 3.74, \quad G_S^d = 2.694, \quad G_S^c = 0.06, \quad G_S^s = 0.64, \quad G_S^b = 0.02. \quad (4.6)$$

Note, however, that there is significant uncertainty and the values might be up to a factor of 2–4 larger as other calculations suggest [41].

With the meson mediation method, the lepton bilinear will couple to an intermediate meson which also couples to the nuclei. Because of the Lorentz structure of the effective operators considered in this work, the only relevant mesons scalar mesons isosinglet $f_0(500)$ and isotriplet $a_0(980)$. The relevant parameters are

$$\alpha_{rS}^{(0,3)} = \frac{1}{4} \times \eta_{rS}^q \begin{cases} \beta_{f_0}, \beta_{a_0} & q = u \\ \beta_{f_0}, -\beta_{a_0} & q = d \\ 0 & q = c, s, b \end{cases}, \quad (4.7)$$

where the parameters are estimated to be $\beta_{f_0} = 1.58$ and $\beta_{a_0} = 2.24$ as in [41].

decay	Br_i^{max}	cutoff scale Λ [TeV]		
		$\Xi_{ij,uu}^u$	$\Xi_{ij,dd}^d$	$\Xi_{ij,ss}^d$
$\tau^- \rightarrow e^- \pi^0$	8.0×10^{-8}	10	10	–
$\tau^- \rightarrow e^- \eta$	9.2×10^{-8}	34	34	7.9
$\tau^- \rightarrow e^- \eta'$	1.6×10^{-7}	42	42	12
$\tau^- \rightarrow e^- K_S^0$	2.6×10^{-8}	–	$7.8 \sqrt{\lambda}$	$7.8 \sqrt{\lambda}$
$\tau^- \rightarrow e^- (f_0(980) \rightarrow \pi^+ \pi^-)$	3.2×10^{-8}	$13 \sqrt{\sin \varphi_m}$	$13 \sqrt{\sin \varphi_m}$	$16 \sqrt{\cos \varphi_m}$
$\tau^- \rightarrow \mu^- \pi^0$	1.1×10^{-7}	9.0–9.6	9.0–9.6	–
$\tau^- \rightarrow \mu^- \eta$	6.5×10^{-8}	36–38	36–38	8.4–8.9
$\tau^- \rightarrow \mu^- \eta'$	1.3×10^{-7}	42–46	42–46	12–13
$\tau^- \rightarrow \mu^- K_S^0$	2.3×10^{-8}	–	$(7.8\text{--}8.3) \sqrt{\lambda}$	$(7.8\text{--}8.3) \sqrt{\lambda}$
$\tau^- \rightarrow \mu^- (f_0(980) \rightarrow \pi^+ \pi^-)$	3.4×10^{-8}	$(12\text{--}14) \sqrt{\sin \varphi_m}$	$(12\text{--}14) \sqrt{\sin \varphi_m}$	$(15\text{--}16) \sqrt{\cos \varphi_m}$

Table 2. Semi-leptonic τ -decays. Experimental constraint on the cutoff scale Λ [TeV] of the effective operators. λ denotes the mixing angle inducing operator mixing as defined in eq. (2.13) and φ_m is the mixing angle between $f_0(500)$ and $f_0(980)$ and is defined in eq. (A.9).

The current best limits on the conversion in these nuclei are $R_{\mu\nu} \leq 4.3 \times 10^{-11}$, 4.6×10^{-11} , 7.0×10^{-13} in ^{48}Ti [16], ^{208}Pb [44], and ^{197}Au [45]. Following ref. [41] we calculate the constraint for the different quark flavours and summarise the results in table 5. Given the experimental constraints, μ - e conversion in gold leads to the most stringent constraint on the cutoff scale Λ . Direct nuclear mediation generally gives stronger constraints, particularly for the heavier quarks. If it would be entirely described by meson exchange mediation, the effective operators with heavier quarks are not constrained, because the form factors of all considered mesons vanish.

4.2 Semi-leptonic τ -decays

Semi-leptonic τ -decays impose another important constraint on operators with τ leptons and light quarks. For the operators considered in this work, the only relevant and well-measured τ -decay modes are decays to pseudoscalar mesons π^0 , η , η' and K_S^0 and to the scalar meson $f_0(980)$ which subsequently decays to pions. We list the kinematically allowed channels and the limit on the branching ratios in table 2, where we quote the current experimental limit on the branching ratios [40].

The decay width for a τ^+ -lepton to a lighter lepton ℓ^+ with mass m_ℓ and a neutral meson $M_{kk}^0 = (\bar{q}_k q_k)$ is given by

$$\Gamma(\tau^+ \rightarrow \ell^+ M_{kk}^0) = \frac{k_M}{32\pi} \frac{m_M^2 \bar{f}_M^2}{m_\tau^2} \left[(m_\tau^2 + m_\ell^2 - m_M^2) |\Xi_\pm|^2 + 2m_\tau m_\ell \text{Re}(\Xi_\pm^2) \right], \quad (4.8)$$

where k_M is the magnitude of the meson 3-momentum in the centre-of-momentum frame

$$k_M^2 = \frac{(m_\tau^2 - (m_\ell + m_M)^2)(m_\tau^2 - (m_\ell - m_M)^2)}{4m_\tau^2} \quad (4.9)$$

and the effective coupling Ξ_{\pm} is defined as

$$\Xi_{\pm} \equiv \Xi_{ij,kl}^{Nu} \cos \varphi \pm \Xi_{ij,kl}^{Nd} \sin \varphi. \quad (4.10)$$

Ξ_+ is the coupling for a scalar meson and Ξ_- is the coupling for a pseudo-scalar meson in the final state. The up-type (down-type) quark content of the meson is $\cos \varphi$ ($\sin \varphi$). The scale-dependent scalar meson decay constant \bar{f}_M is defined in eq. (A.1). The partial decay width will be compared with the total decay width $\Gamma_{\tau} = \tau_{\tau}^{-1} = 2.27 \times 10^{-9} \text{ MeV}$.

Besides the pseudoscalar mesons, we consider the scalar meson $f_0(980)$, which dominantly decays to two pions with a branching ratio $\text{Br}(f_0(980) \rightarrow \pi^+ \pi^-) = 0.46$ [46]. We parameterize its quark content by the mixing angle φ_m , which is defined in eq. (A.9).

Our limits are quoted in table 5. The result only very weakly depends on the phase of the of the Wilson coefficient $\Xi_{ij,kl}^{Nu,Nd}$ for hierarchical lepton masses and generally leads to a correction at the level of

$$\frac{4m_{\ell_i}m_{\ell_j}}{m_{\ell_i}^2 + m_{\ell_j}^2} \sim 4 \frac{\min\{m_{\ell_k}\}}{\max\{m_{\ell_k}\}} \quad (4.11)$$

percent compared to the total decay width, which amounts to about 1% (10%) in case of an electron (muon) final state. Thus it is below the precision for an electron in the final state, but we quote the range in case of a muon in the final state. The strongest limits are from decays to $\eta^{(\prime)}$ and $f_0(980)$ mesons because the product $m_M \bar{f}_M$ is relatively large.

4.3 Leptonic neutral meson decays

Another important class of constraints comes from LFV neutral meson decays. The decay width of a meson $M_{kl}^0 = (\bar{q}_k q_l)$ can be expressed as

$$\Gamma(M_{kl}^0 \rightarrow \ell_i \ell_j) = \frac{k_{\ell}}{16\pi} \bar{f}_M^2 \left[(m_M^2 - m_{\ell_i}^2 - m_{\ell_j}^2) |\Xi_-|^2 + 2m_{\ell_i}m_{\ell_j} \text{Re}(\Xi_-^2) \right], \quad (4.12)$$

where k_{ℓ} is the magnitude of the lepton 3-momentum in the centre-of-momentum frame,

$$k_{\ell}^2 = \frac{(m_M^2 - (m_{\ell_i} + m_{\ell_j})^2)(m_M^2 - (m_{\ell_i} - m_{\ell_j})^2)}{4m_M^2} \quad (4.13)$$

and the effective coupling Ξ_- is defined in eq. (4.10). The experimental constraints on the cutoff scale Λ [TeV] of the effective operators are collected in table 3. The top part of the table lists the direct constraints on the operators with the same quarks in eq. (2.6), while the lower part summarises indirect constraints on the operators from operator mixing induced by their creation from gauge invariant operators. These constraints are parameterised by λ , which is defined in eq. (2.13). It is clear that we can place the strongest limit on operators with $e\mu$.

4.4 Leptonic charged meson decays

As discussed in section 2 there are also effective four fermion interactions which contribute to different charged meson decays. Many charged meson decays have already been measured

decay	Br_i^{max}	cutoff scale Λ [TeV]

$B^0 \rightarrow \mu^\pm \tau^\mp$	2.2×10^{-2}	—	$0.18\sqrt{\lambda}$	—	—	$0.12\sqrt{\lambda}$

Table 3. Leptonic LFV meson decays. Experimental constraint on the cutoff scale Λ [TeV] of the effective operators. The processes listed in the top part of the table directly constrain the operators with the same quarks in eq. (2.6), while the ones in the lower part indirectly constrain the operators with the same quarks via the operators generated by operator mixing as defined in eq. (2.13).

and can be used to indirectly constrain the operators in eq. (2.6). In particular the decays of π^+ and K^+ have been measured to high precision,

$$\begin{aligned}
 R_\pi &= \frac{\text{Br}(\pi^+ \rightarrow e^+ \nu)}{\text{Br}(\pi^+ \rightarrow \mu^+ \nu)} = (1.230 \pm 0.004) \times 10^{-4}, & \text{Br}(\pi^+ \rightarrow \mu^+ \nu) &= 0.9998770 \pm 0.0000004, \\
 R_K &= \frac{\text{Br}(K^+ \rightarrow e^+ \nu)}{\text{Br}(K^+ \rightarrow \mu^+ \nu)} = (2.489 \pm 0.011) \times 10^{-5}, & \text{Br}(K^+ \rightarrow \mu^+ \nu) &= (63.55 \pm 0.11) \times 10^{-2}.
 \end{aligned}
 \tag{4.14}$$

However we expect our calculation to be precise at the level of 5% and thus our theoretical precision does not match the experimental precision. A precise treatment would require the inclusion of higher order corrections in chiral perturbation theory, which has been done for the SM contribution in ref. [47]. As there are interference terms between the SM and the new physics contribution, it is not possible to use the precise SM result directly. We do not attempt to include higher-order corrections to pion and kaon decays, but conservatively require that the predicted value taking the operator and the SM contribution into account is within 5% of the experimental value. Given that the precision of these measurements is 0.3% (0.4%) for R_π and R_K as well as $4 \times 10^{-5}\%$ (0.17%) for pion (kaon) decay to a muon and a neutrino, we naively (neglecting cancellations) expect that it is possible to increase the limit on the cutoff scale from R_π , R_K and $\text{Br}(K^+ \rightarrow \mu^+ \nu)$ by a factor of two. Similarly taking the experimental precision into account, it might be possible to improve the limit from $\text{Br}(\pi^+ \rightarrow \mu^+ \nu)$ by up to a factor 20.

Table 4. Experimental constraint on the cutoff scale Λ [TeV] of the effective operators from LFV leptonic charged meson decays. The second column indicates the relevant experimental constraint. The third and fourth columns give the constraint in TeV. The index of Λ denotes the relevant leptons of the operator. The final state charged lepton in each process is right-handed and thus corresponds to the second index of the Wilson coefficient. Measured branching ratios are imposed at the 2σ level unless otherwise specified. The check marks [✓] indicate the constrained operator.

The decay width for charged meson decay $M_{kl}^+ = (u_k \bar{d}_l)$ in the limit of massless neutrinos is given by

$$\begin{aligned}
 & \Gamma(M_{kl}^+ \rightarrow \ell_i^+ \nu) \\
 &= \frac{k_\ell}{8\pi m_M^2} (m_M^2 - m_{\ell_i}^2) \left[2G_F^2 f_M^2 m_{\ell_i}^2 |V_{kl}|^2 \right. \\
 & \quad + \frac{m_M^2 \bar{f}_M^2}{4} \sum_j \left| \Xi_{ij,kl}^{Cu} - \Xi_{ij,kl}^{Cd} + \frac{y_{\ell_i} (y_{u_k} + y_{d_l})}{m_W^2} U_{ij}^* V_{kl}^* \right|^2 \\
 & \quad \left. - \sqrt{2} G_F m_{\ell_i} m_M \bar{f}_M f_M \left(\frac{y_{\ell_i} (y_{u_k} + y_{d_l})}{m_W^2} |V_{kl}|^2 + \text{Re} \left(\sum_j \left(\Xi_{ij,kl}^{Cu} - \Xi_{ij,kl}^{Cd} \right) U_{ij} V_{kl} \right) \right) \right]
 \end{aligned} \tag{4.15}$$

with the 3-momentum k_ℓ defined in eq. (4.13). The Yukawa couplings of the charged fermions are defined as $y_{u_k} \equiv m_{u_k}/v$, $y_{d_l} \equiv m_{d_l}/v$ and $y_{\ell_i} \equiv m_{\ell_i}/v$ with the vacuum expectation value $v = 174 \text{ GeV}$. Finally the meson decay constant f_M and the scale-dependent scalar meson decay constant \bar{f}_M are both given in appendix A.

All results are summarised in table 4. The first column lists the observable, like the ratio $R_{\pi,K}$ and the branching ratios. The second column indicates the used experimental constraint. Note that the calculation is limited by the theory error in case of pions and

Figure 3. Signatures at hadron colliders.

Kaons. We require the new physics contribution to deviate from the experimental result by less than 2σ . The third and fourth column list the obtained lower limit on the cutoff scale Λ_{ij} , where the indices indicate the two leptons of the operator. Check marks $[\checkmark]$ in the fifth to ninth column indicate the operators, which are constrained by the considered process. The charged lepton in the final state of the different processes is right-handed, i.e. the one with the index j of the Wilson coefficient. Despite our crude calculation the strongest constraints on the cutoff scale Λ are extracted from the ratios R_π and R_K , which could be improved with a more precise calculation. However they are outperformed by μ - e conversion in nuclei.

5 LHC search

At colliders, the four fermion interaction $\bar{\ell}_{Li}\ell_{Rj}\bar{q}_kq_k$ can lead to the charged lepton flavour violating processes,¹

$$pp \rightarrow \ell_i \ell_j + \text{jets} . \quad (5.1)$$

We show the Feynman diagrams contributing to this process up to one jet in figure 3, including the leading order contribution in figure 3a and the next-to-leading order contributions in figures 3b–3d.

CDF and D0 reported on their search for $e\mu$ final states from s -channel heavy resonance decays in refs. [48, 49]. There are also rich studies about charged lepton flavour violating processes at the LHC. ATLAS has searched for $Z \rightarrow e\mu$ in ref. [50]. Similarly LFV Higgs decay has also been studied in refs. [19, 20]. Both ATLAS and CMS have performed search for heavy resonances decay to $e\mu$ in refs. [51, 52]. ATLAS has also expanded their search to include $e\mu$, $e\tau$ and $\mu\tau$ in [53]. These analyses examined the $e\mu$, $e\tau$ or $\mu\tau$ invariant mass spectrum for the presence of a heavy particle. They found no evidence of new physics and gave model-dependent limits on the mass of the heavy resonances for given couplings. All these searches looked for LFV processes *inclusively*, i.e. including extra jets. In ref. [54] ATLAS searched *exclusively* for final states with a LFV $e\mu$ pair and zero jet for t -channel \tilde{t} exchange. Note that in most analyses well-defined and properly reconstructed jets have $p_T \gtrsim 30$ GeV.

¹The other four fermion interaction with a neutrino will lead to the signature of a mono-lepton with missing energy, which has a large SM background from W -boson production and it will thus not lead to competitive limits. Hence we do not consider it for the LHC study.

Figure 4. The distribution of the $e\mu$ invariant mass at parton level at $\sqrt{s} = 7$ TeV. The production cross section of each operator has been normalised to the same value.

We will take the most up-to-date *inclusive* and *exclusive* analyses for a pair of oppositely charged flavour off-diagonal leptons, i.e. the 8 TeV search for $e\mu$, $e\tau$ and $\mu\tau$ with 20.3 fb^{-1} integrated luminosity in ref. [53] and the 7 TeV search for $e\mu$ with 2.08 fb^{-1} integrated luminosity in ref. [54]. The searches have quite distinctive SM background because of the requirement on jets, which will be elaborated in section 5.1. With Monte Carlo simulation and the aid of hepdata, we will recast both searches and extract the LHC limits for the effective operators chosen in this work.

Before we move on to the details of the simulation, we want to stress that the LHC limits depend on the quark flavour in a not-so-trivial manner. Because of the parton distribution functions, the p_T distribution and the invariant mass distribution of the lepton pairs in the final states are also different for operators with different quark flavours even if the total production cross sections at the LHC were the same. As an example, we plot invariant mass distribution of $e\mu$ final states in a pp collider at $\sqrt{s} = 7$ TeV in figure 4. It is easy to see that the distributions are quite similar for the two lighter flavours u and d , plotted with a black solid and blue dashed line respectively, and for the heavier ones s , c and b shown with a gray solid, green dashed, and red dot-dashed line respectively.

5.1 Signal and background

The signals for the 7 TeV $e\mu$ exclusive analysis dominantly come from the tree-level process in figure 3a. Since the exclusive search rejects any events with a well-fined jet, we neglect all next-to-leading order contributions for the signals. The relevant operators are implemented in *FeynRules 2.0* [55] to generate output model files in UFO format. The signal events are generated in *MadGraph 5* [56] at leading order with parton distribution function nn23lo1. The parton level events are subsequently piped to *PYTHIA 8.2* [57] for showering and hadronization. The detector effects are simulated using *Delphes 3* [58]. For operators with $e\tau$ and $\mu\tau$, the τ -lepton could also decay leptonically and gives an $e\mu$ final state. However,

these processes are suppressed by the leptonic branching ratios of τ and lead to really poor limits. Thus we will only consider operators with $e\mu$ for the 7 TeV analysis.

Similar to the 7 TeV search, the signal of the inclusive search at 8 TeV also comes mainly from the tree level diagram in figure 3a. The next-to-leading order contribution can result in a K -factor. Assuming a uniform K -factor, the lower limit on the UV cutoff will be scaled up by $K^{\frac{1}{4}}$, which only improves the limits by a few percent. So for the 8 TeV analysis in this work, we will take the leading order contribution from the tree level diagram and assume a unity K -factor for simplicity. The signal samples are generated with the same tool chain.

The major SM processes that can lead to $e\mu$ final states include $t\bar{t}$, WW , and $Z/\gamma^* \rightarrow \tau\tau$. The $t\bar{t}$ pair decays to $e\mu$ via W bosons and is always accompanied with two hard b -jets. The other two channels, WW and $\tau\tau$, give rise to a LFV lepton pair through leptonic W and τ decay, which usually have large missing transverse energy, E_T^{miss} , because of the neutrinos in the final states. So in the 7 TeV analysis, these background events are quite efficiently eliminated by the selection requirements for zero jet and small E_T^{miss} . Because jets can be misidentified as leptons, W/Z plus jets and multi-jets also contribute. This type of background is denoted as fake background and estimated from data at the ATLAS search. Other subdominant background includes WZ/ZZ , single top and $W/Z + \gamma$. For both 7 TeV and 8 TeV analysis, WW , $Z/\gamma^* \rightarrow \tau\tau$ and $t\bar{t}$ make up around 90% of the background. Because of the strict selection rules, the background for the 7 TeV analysis is much cleaner than the 8 TeV one. This ensures a good limit even with a much lower integrated luminosity at 7 TeV. For the $e\tau$ and $\mu\tau$ search at the 8 TeV, the background is dominated by the Drell-Yan process $Z/\gamma^* \rightarrow \mu\mu/\tau\tau$ and the fake background. The contribution from the fake background can be as much as 50%.

We use *MadGraph 5* at NLO to generate the background sample for WW , $Z/\gamma^* \rightarrow \tau\tau$ and $t\bar{t}$, where showering and hadronization is handled with *Herwig 6* [59]. Detector effects are simulated with *Delphes 3*. Our simulated background samples agree with the experimental analysis. However, the simulation and the estimation of the fake background requires the analysis on the actual experimental data, which is way beyond the scope of this work. Therefore, we will use the experimental measurements to extract the limits at both 7 TeV and 8 TeV.

For the 14 TeV LHC run, we will only try to project the limit on the operators with $e\mu$ because of the non-negligible fake background for other final states. Of the two searching strategies, we will choose the one in the 7 TeV analysis, which gives a much cleaner background and thus a better limit for the same dataset. So we will make use of the tool chain described here for the WW and $Z/\gamma^* \rightarrow \tau\tau$ background estimate. We assume the contribution from the fake background in the selected sample at 14 TeV will be slightly less than that from $Z/\gamma^* \rightarrow \tau\tau$ as in the 7 TeV analysis. In our simulation we will consider an integrated luminosity of 300 fb^{-1} .

5.2 Event selection

For the 7 TeV and 8 TeV search, we take the same selection requirements as in the ATLAS analysis. The event selection requires a pair of oppositely charged leptons. Electrons

should have $E_T > 25$ GeV and satisfy a set of stringent identification requirements referred as *tight*. We implement the *tight* identification through the electron efficiency in *Delphes 3* as in ref. [60]. Electrons are rejected if they lie outside the pseudorapidity regions $|\eta| < 1.37$ or $1.52 < |\eta| < 2.47$. Similarly muons are required to have $p_T > 25$ GeV and $|\eta| < 2.4$. Tau candidates should also have $E_T > 25$ GeV and lie in the proper pseudo-rapidity range $|\eta| < 2.47$ and $|\eta| > 0.03$. In addition, we implement the lepton isolation requirements: the scalar sum of the track p_T within a cone of $\Delta R = 0.2(0.4)$ around the lepton is less than 10% (6%) of the lepton's p_T for the 7 (8) TeV search; similarly the sum of E_T within the cone of $\Delta R = 0.2$ is less than 15% (6%) of the lepton's E_T for the 7 (8) TeV search. Jets are reconstructed using the anti- k_t algorithm with a radius parameter of 0.4. In the 7 TeV search any events with jets that have $p_T > 30$ GeV or $E_T^{\text{miss}} < 25$ GeV are rejected. Additionally the invariant mass of the lepton pair should be bigger than 100 (200) GeV and the azimuthal angle difference between them should be bigger than 3 (2.7) for the 7 (8) TeV search.

For the 14 TeV projection, we will impose the following cuts on lepton transverse momentum, p_T , and the total missing transverse energy: $p_T(\ell) > 300$ GeV and $E_T^{\text{miss}} < 20$ GeV, in addition to the same cuts on the azimuthal angle $\Delta\phi(e, \mu) > 3.0$ and the lepton identification and isolation requirements. After the selection, the only SM background is from WW , while $\tau\tau$ contribution drops much faster with increasing dilepton invariant mass. With the assumption that the contribution from fake background is less than that from $\tau\tau$, we can also neglect the fake background in the 14 TeV projection.

5.3 Limit setting and results

We use maximum likelihood estimator for limit setting at the 7 and 8 TeV searches. The observed invariant mass distributions of the $e\mu$ pair as well as the SM background for the 7 and 8 TeV analyses are taken from hepdata. The likelihood function for each bin is defined as

$$\mathcal{L}_i(\mu, \tilde{\theta}_i | n_i) = \mathcal{P}(n_i | \mu s_i + b_i) \mathcal{G}(\tilde{\theta}_i, 0, 1), \quad (5.2)$$

where \mathcal{P} and \mathcal{G} are Poisson and Gaussian functions. s_i , b_i and n_i are the predicted signal, SM background and the observed events in the i -th bin. The parameter μ is the signal strength and $\tilde{\theta}_i$ is the nuisance parameter. The total likelihood function is the product of \mathcal{L}_i in each bin. This limit setting method is tested with the hypothesis as described in the 7 and 8 TeV ATLAS analyses and the results agree within percent level.

For the 14 TeV projection, we will perform the same limit setting procedure with the binned invariant $e\mu$ mass spectrum from 600 GeV to 1 TeV with bin width of 50 GeV as well as an over-flow bin. For the 14 TeV projection, we will estimate the experimental reach simply with

$$\text{Significance} = \frac{S}{\sqrt{S + (\Delta S)^2 + (\Delta B)^2}}, \quad (5.3)$$

where S and B denote the number of signal and background events. ΔS and ΔB parameterize the systematic uncertainties, $\Delta S = 10\%S$ and $\Delta B = 10\%B$.

$\bar{q}q \backslash \bar{\ell}_i \ell_j$	$\bar{e}\mu$			$\bar{e}\tau$	$\bar{\mu}\tau$
	7 TeV	8 TeV	14 TeV	8 TeV	8 TeV
$\bar{u}u$	2.6	2.9	8.9	2.4	2.2
$\bar{d}d$	2.3	2.3	8.0	2.1	1.9
$\bar{s}s$	1.1	1.4	4.0	0.95	0.88
$\bar{c}c$	0.97	1.3	3.6	0.82	0.78
$\bar{b}b$	0.74	1.0	2.7	0.63	0.61

Table 5. Constraints from the LHC searches on the cutoff scale Λ [TeV] at the 7 and 8 TeV search. The 14 TeV projection is also listed for the $e\mu$ final state.

We list the current limits and future projection at the 14 TeV run in table 5. Note that the 8 TeV search does not result in much better limits even with a higher beam energy and 10 times more data than the 7 TeV one, simply due to the large background. The limits for $e\tau$ and $\mu\tau$ are both weaker than the $e\mu$ channel at 8 TeV as a result of the low τ -tagging rate and higher fake background.

6 Discussion

In figure 5 we compare the most stringent constraints from precision experiments and the LHC. If the constraint depends on a free parameter like the phase of the Wilson coefficient or a mixing angle, we show the possible constraints in a band and include the second-most stringent constraint as well. For completeness, we kept the constraints from R_π and R_K , since they suffer from their theoretical uncertainty and can be further improved with a more detailed calculation by a factor of a few. Operators with different lepton combinations are separated by a gray vertical line. The figure shows the limits on operators with the quarks u, d, s, c, b ordered from left to right in each of the blocks. The current 8 TeV LHC constraints are denoted by a solid red line and the future (14 TeV) sensitivity by a dashed orange line. The constraints from μ - e conversion are shown in green indicating the range between direct nuclear mediation and meson exchange mediation. Blue lines indicate limits from τ -decays to a charged lepton and a neutral pseudoscalar mesons besides f_0 , which is shown in purple. It depends on the undetermined mixing angle φ_m between the different quark compositions. Finally, constraints from leptonic charged meson decays are shown in gray. The limits from leptonic neutral meson decays were generally weaker than the presented limits and are thus not included in the figure.

For operators with $e\mu$ across all quark flavours, the limit from μ - e conversion in nuclei clearly outperforms any other limit. Even its current limit on Λ assuming direct nuclear mediation is two orders of magnitude higher than that from the 14 TeV projection of the LHC. The limits certainly will be further improved by the two proposed experiments, Mu2E [12, 13] at FNAL and COMET [14, 15] at J-PARC, which aim to improve the sensitivity of μ - e conversion in ^{48}Ti down to 10^{-16} , and possibly even to 10^{-18} in a future proposed experiment PRISM/PRIME [14, 15]. For $e\tau$ and $\mu\tau$, pion and Kaon decays and semi-leptonic τ decays places the strongest constraints for the light quark flavours. The

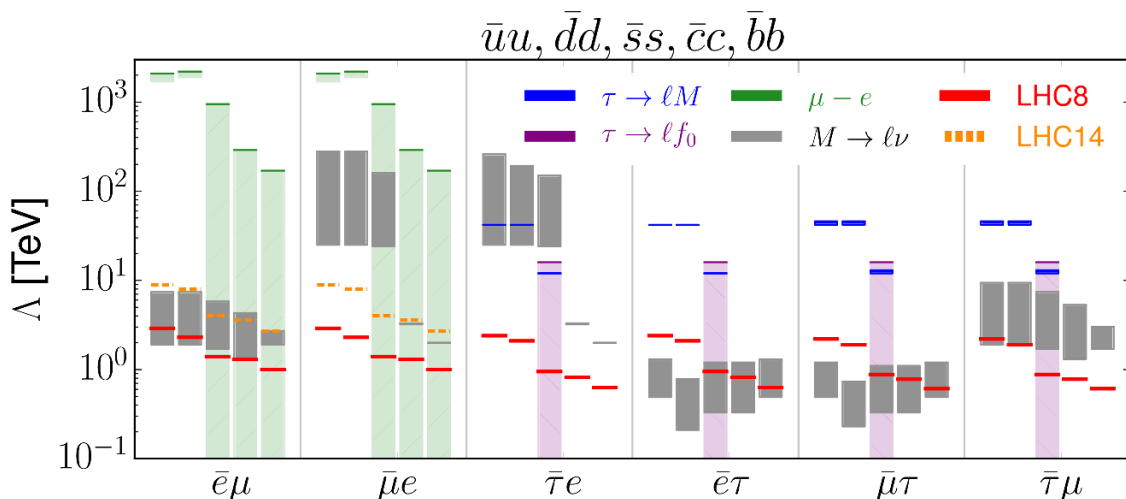

Figure 5. Summary plots of most stringent limits from precision experiments and the LHC. See the text for a detailed explanation.

limits from τ decays will be further improved at the Belle-II experiment [61]: Belle-II aims to increase the sensitivity on the branching fraction by two orders of magnitude. Note that constraints from precision measurements for $\bar{u}u$ and $\bar{d}d$ are quite similar, which can be easily explained with the isospin symmetry.

However, the constraints on the operators with heavy quark flavours are generally weaker. That is exactly where the LHC comes into play. With the 8 TeV LHC search, the collider limit is competitive with constraints from τ -decays and charged meson decays for operators with $\bar{c}c$ and $\bar{b}b$ and a right-handed τ -lepton. In particular it does not depend on the phase of the Wilson coefficient. The limits from charged meson decays feature an interference with the SM contribution and thus depend on the phase of the Wilson coefficient. Using the 8 TeV LHC data, we set limits of 600–800 GeV on the cutoff scale Λ for LFV operators with right-handed τ leptons and we expect that those limits can be further improved with more integrated luminosity, similar to projected sensitivity for the $e\mu$ channel at 14 TeV with 300 fb^{-1} . In case of the $e\mu$ channel we find that the sensitivity of the LHC can be improved by a factor of 2.7–3.5.

Finally we want to address the validity of the effective operator descriptions at the LHC. When the momentum transfer Q_{tr} in the interaction is comparable to the heavy mediator of mass M in the UV completion of the effective theory, the effective operator description is no longer a good approximation. The UV cutoff scale Λ is related to the mass of the heavy mediator with

$$M = \Lambda \sqrt{g_q g_l}, \quad (6.1)$$

where g_q (g_l) denote the couplings between the heavy mediator and the quarks (leptons). To properly preserve the validity of the effective operators, a procedure referred as truncation can be conducted when $Q_{\text{tr}} > M$, i.e. the event is discarded [62]. So if we take the optimistic limit $g_q = g_l = 4\pi$, the heavy mediator mass should be at least $\gtrsim 7.7 \text{ TeV}$ for the 8 TeV search and the results are surely valid. Even with relatively conservative

option $g_q = g_l = 1$, the LHC limit is still quite sound, because the LHC analyses we use in this work rely mostly on events with smaller momentum transfer. Moreover, if very small values of g_q and g_l are chosen, we are bound to return to the UV completions, which is a completely different type of study not meant to be contained in this work.

7 Conclusions

From the comprehensive case study in this work, we see that precision measurements and the LHC study are indeed complementary. Which experiment gives the best reach depends on both the quark flavour and the lepton pair in the operator. For light quarks u , d and s , precision measurements clearly outperform the LHC irrespective of the charged lepton flavour. However, the LHC becomes competitive for heavier quarks, c and b , and there is an interesting interplay between the two approaches to obtain limits on LFV operators with two quarks and two leptons. Operators with $e\mu$ are still highly constrained by precision measurements, particularly μ - e conversion in nuclei, but the LHC competes for LFV operators with right-handed τ leptons and can set limits independent of the phase of the Wilson coefficient. We set a lower limit of 600–800 GeV on the cutoff scale of all these operators.

In this study we restricted ourselves to scalar operators and did not consider operators with top quarks. For other Lorentz structures we expect similar limits from the LHC, but the limits from the precision experiments have to be reevaluated. In case of top quarks, there are no direct limits from precision experiments, although operator mixing will lead to some constraint. We expect that a similar analysis of the collider phenomenology can set new interesting limits in addition to constraints from flavour violating top decays. Finally we only considered non-resonant searches and did not consider possible underlying UV completions. A complementary study of simplified models, where the operators are opened up, might lead to more stringent, although model-dependent, limits.

Acknowledgments

We thank Martin Holthausen for collaboration during the initial stages of this project and Tong Li, Fei Gao, Lei Wu, Aldo Saavedra and Bruce Yabsley for useful discussions. This work was supported in part by the Australian Research Council. We acknowledge the use of `matplotlib` [63] and `ipython` [64].

A Mesons

The quark bilinear in the operator we choose to study determines that the only mesons involved in the LFV processes are either neutral scalars or pseudoscalars. The decay constants f_M for scalar (S) and pseudo-scalar (P) mesons are defined as

$$\langle 0 | \bar{q}^i \gamma^\mu q^j | S(p) \rangle = f_S p^\mu, \quad \langle 0 | \bar{q}^i q^j | S(p) \rangle = m_S \bar{f}_S, \quad (\text{A.1a})$$

$$\langle 0 | \bar{q}^i \gamma^\mu \gamma_5 q^j | P(p) \rangle = f_P p^\mu, \quad \langle 0 | \bar{q}^i \gamma_5 q^j | P(p) \rangle = m_P \bar{f}_P = m_P f_P \frac{m_P}{m_q^i + m_q^j}. \quad (\text{A.1b})$$

$f_0(980)$	990		40–100	★	★

Table 6. Relevant data for the scalar and pseudoscalar mesons studied in this work. Besides the last meson $f_0(980)$ which has $J^{PC} = 0^{++}$, all mesons are pseudoscalar mesons with $J^{PC} = 0^{-+}$ according to the quark model assignment. We list the decay constants for most mesons assuming isospin symmetry to relate the decay constants of charged mesons with the corresponding neutral meson. ★ Please refer to the text for the decay constants of $\eta^{(\prime)}$ and $f_0(980)$.

The scale-dependent scalar decay constants \bar{f}_M are related to the decay constants f_M via the equations of motion.

We use the experimental values (where available) for the pseudoscalar decay constants and the quark masses in ref. [40]

$$\begin{aligned} \bar{m} &= \frac{m_u + m_d}{2} = 3.5_{-0.2}^{+0.7} \text{ MeV}, & m_c &= (1.275 \pm 0.025) \text{ GeV}, \\ m_s &= (95 \pm 5) \text{ MeV}, & m_b &= (4.18 \pm 0.03) \text{ GeV} \end{aligned} \quad (\text{A.2})$$

to obtain the scale-dependent scalar decay constants. All decay constants are listen in table 6 except for the states $\eta^{(\prime)}$ and $f_0(980)$, where the decay constants depend on a mixing angle.

The pseudo-scalars η and η' mix with each other and are a mixture of $|s\bar{s}\rangle$ and the isospin singlet $|q\bar{q}\rangle \equiv (|u\bar{u}\rangle + |d\bar{d}\rangle)/\sqrt{2}$ and their decay constants can be parameterised in terms of two decay constants $f_{q,s}$ and two mixing angles $\phi_{q,s}$

$$\begin{pmatrix} f_\eta^q & f_\eta^s \\ f_{\eta'}^q & f_{\eta'}^s \end{pmatrix} \equiv \begin{pmatrix} f_q \cos \phi_q & -f_s \sin \phi_s \\ f_q \sin \phi_q & f_s \cos \phi_s \end{pmatrix}. \quad (\text{A.3})$$

In the FKS formalism [65–67], the mixing angles coincide $\phi_s = \phi_q \equiv \phi$ and glueball admixtures are neglected. The vector decay constants $f_{q,s}$ and the mixing angle ϕ are

given by [65, 67]

$$f_q = (1.07 \pm 0.02)f_\pi, \quad f_s = (1.34 \pm 0.06)f_\pi, \quad \phi = (39.3 \pm 1.0)^\circ. \quad (\text{A.4})$$

The corresponding vector decay constant for the η and η' meson are

$$\begin{aligned} \bar{f}_\eta^q &= f_q \cos \phi \simeq 110 \text{ MeV}, & \bar{f}_{\eta'}^q &= f_q \sin \phi \simeq 88 \text{ MeV}, \\ \bar{f}_\eta^s &= -f_s \sin \phi \simeq -110 \text{ MeV}, & \bar{f}_{\eta'}^s &= f_s \cos \phi \simeq 130 \text{ MeV}. \end{aligned} \quad (\text{A.5})$$

The meson masses given in table 6 the scalar decay constants are thus

$$\bar{f}_\eta^q = f_q \cos \phi \frac{m_\eta}{2\bar{m}} \simeq 8400 \text{ MeV}, \quad \bar{f}_{\eta'}^q = f_q \sin \phi \frac{m_{\eta'}}{2\bar{m}} \simeq 12000 \text{ MeV}, \quad (\text{A.6})$$

$$\bar{f}_\eta^s = -f_s \sin \phi \frac{m_\eta}{2m_s} \simeq -320 \text{ MeV}, \quad \bar{f}_{\eta'}^s = f_s \cos \phi \frac{m_{\eta'}}{2m_s} \simeq 680 \text{ MeV}. \quad (\text{A.7})$$

Finally, in the case of $f_0(980)$ with mass $m_{f_0(980)} = 990 \pm 20 \text{ MeV}$ [40] the scale-dependent decay constant \bar{f}_M is given by [68]

$$\bar{f}_{f_0(980)} = 370 \pm 20 \text{ MeV}. \quad (\text{A.8})$$

In the simple quark picture $f_0(980)$ together with $f_0(500)$ are a mixture of $|s\bar{s}\rangle$ and the isospin singlet $|q\bar{q}\rangle$. The exact mixing angle φ_m between the $f_0(500)$ and the $f_0(980)$ meson is not known yet. See ref. [69] for a list of experimental results. Note however that it is unclear whether the description in the simple quark picture is actually correct or whether the $f_0(980)$ is a multi-quark state [40]. We will assume the simple quark model and parameterize our result in terms of the mixing angle φ_m between $|s\bar{s}\rangle$ and the isospin singlet $|q\bar{q}\rangle$

$$\begin{pmatrix} |f_0(980)\rangle \\ |f_0(500)\rangle \end{pmatrix} = \begin{pmatrix} \cos \varphi_m & \sin \varphi_m \\ -\sin \varphi_m & \cos \varphi_m \end{pmatrix} \begin{pmatrix} |s\bar{s}\rangle \\ |q\bar{q}\rangle \end{pmatrix}. \quad (\text{A.9})$$
